Loglinear Regression In loglinear

## File Type PDF Interpreting The Coefficients Of Loglinear Models

regression analysis is used to describe the pattern of data in a contingency table. A model is constructed to predict the natural log of the frequency of each cell in the contingency table. For a 2x2 table, that means the model is  $\ln f_{ij} = b_r * \text{row} + b_c * \text{col} + b_{i * j} * \text{int} + a$

$\frac{1}{100}$ ). Hence the interpretation that a 1% increase in  $x$  increases the dependent variable by the coefficient/100. Once again let's fit the wrong model by failing to specify a log-transformation for  $x$  in the model syntax.

The standard interpretation of coefficients in a regression analysis is that a one unit change in the independent variable results in the respective regression coefficient change in the expected value of the dependent variable while all the predictors are held constant. Interpreting

You can estimate this model with OLS by simply using natural log values for the dependent variable (Y) and the original scale for the independent variables (X). It's known as a log-linear model. After estimating a log-linear model, the coefficients can be used to determine the impact of your independent variables (X)
